Control Implementations

Control unit design:

- **Hardwired control**
  - expressed as a finite state machine (state diagrams & transitions between states)
  - implemented with PLAs (programmable logic arrays) & random logic
  - good if the number of states is "small" (RISC architectures)
- **Microprogrammed control**
  - expressed as a "micro" program
  - implemented with read-only memory (ROM) of simple instructions (**microcode** instructions)
  - provides structure & modularity when the number of states is "large" (CISC architectures)

Finite State Machine

Sequential & combinational logic function that consists of:

- set of **inputs**
- **output function**: maps current state (Moore machine) or current state & inputs (Mealy machine) to a set of outputs
- **next state function**: maps current state & inputs to a new state

Finite state machine for CPU control:

- state = a step in the execution cycle
- input = opcode & func fields
- output = control signals that drive the datapath that cycle

Microprogramming -- Basic Idea

Microprogramming: designing control that implements machine (architecture) instructions in terms of simpler microinstructions

- **microinstruction**: specifies the control signals that must be asserted in a given cycle
- fields in a microinstruction are represented to the human symbolically (just like assembly language for machine instructions)
- each machine instruction is emulated by a sequence of microinstructions
- **microcode** or **microprogram**: set of all microinstructions that control processor execution

Implemented by a simple auxiliary micro datapath & micro control unit that generates signals for the main datapath

- "computer within a computer"
- micro datapath fetches microinstructions
  - ROM address of the current instruction is in the microPC
- micro control unit sends signals to the main datapath

Microinstruction Encoding

Multiple fields, multiple values per field

- width of field is determined by the number of values

Encoding the microinstruction:

- design so that each field specifies a non-overlapping set of control signals
  - signals that are not asserted together can share the same field
- don't put so many signals into the same field that it needs complex interpretation to get the individual signal values that will drive the macro datapath
- 2 different style extremes
  - **horizontal microcode**: 1 field for each value
    - no decoding
    - very wide microinstructions
  - **vertical microcode**:
    - very highly encoded
    - much narrower microinstructions
- a control signal can't be set to more than one value in a microinstruction
  - microassembler makes sure that conflicting signals aren't generated in a microinstruction

Microsequencing

Choosing the next microinstruction

(1) the next sequential microinstruction

- increment the microPC

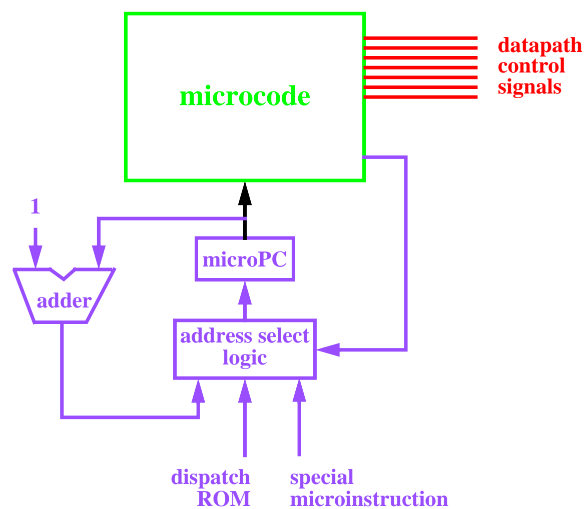
(2) begin a new machine instruction

- branch to the microinstruction that controls instruction fetching

(3) have multiple options that depend on some control unit input

- dispatch through a ROM of microinstruction target addresses
- R2000 uses this for switching on the opcode

Block Diagram



Microcode for R2000

Label	ALU Control	SRC 1	SRC 2	Register control	Memory	PCWrite control	Sequen-cing
fetch	add	PC	4		read PC	ALU	seq
	add	PC	extshft	read			dispatch 1
mem1	add	A	extend				dispatch 2
lw2					read ALU		seq
				write MDR			fetch
sw2					write ALU		fetch
rfmt1	func code	A	B				seq
				write ALU			fetch
beq1	subt	A	B			ALU-Out: cond	fetch
jump1						jump address	fetch

Pentium Pro

Implementation

- PLA (hardwired) for RISC-like instructions
- microcode for more complex instructions
    - ~8000 microinstruction ROM
    - microsubroutines (nanocode)

Execution times are similar to RISC machines

- most instructions are RISC-like

A Comparison

Distinctions used to be clearer

- microinstructions in ROM faster than machine instructions in RAM (memory)
  - an argument for CISC also
- microcode could be expressed symbolically
  - microcode was easier to express; hardwired random logic was too complicated to specify for a CISC architecture
- microcode could be easily changed
  - $\Rightarrow$ new instructions could be easily added
  - $\Rightarrow$ bugs could be easily fixed
  - $\Rightarrow$ specifying the architecture & building the implementation could go on in parallel
- microcode was more modular
  - different ROMs could be used to emulate older architectures
  - microsubroutines could be used

A Comparison

Both have similar performance

- microcode ROM no longer has the big speed advantage over macro instructions in RAM since instructions are cached
- PLA may be smaller & therefore somewhat faster than a ROM

Both have the same difficulty of design & debugging

- CAD tools allow hardwired control to be specified symbolically
  - same difficulty in specifying & debugging control
  - same difficulty in adding instructions to an existing ISA
- faster machines provide a more detailed simulation & therefore fewer bugs

Could probably use multiple PLAs as easily as multiple ROMs to allow several implementations of the same architecture on the same machine
(good for backwards compatibility)

Still the case that:

- hardwired control used for simple, regular instructions
- microcode used for complex, variable-length instructions
