The 3 C's

Taxonomy of misses

Misses can be classified as:

Compulsory (or cold)

- caused by the first reference to a block
- how to reduce:

Capacity

- the cache is not big enough to hold all the blocks that were referenced
- how to reduce:

Conflict

- the referenced blocks all map to the same set & all the blocks in the set are valid
- how to reduce:

Design Trade-offs

Cache size

the bigger the cache,

+

-

-

Calculating cache size

- cache size: # bytes of **data**
  - different than the number of bits of memory needed to build a cache (data, tags, state)
- # bytes/block * associativity * # sets
- example: 64KB cache, 32B blocks, 2-way set-associative
  - what is the cache size?
  - how many bits does it take to implement the cache?

Design Tradeoffs

Block size

large blocks

+

+

+

-

-

-

Design Tradeoffs

Block size

large blocks

+ can take better advantage of spatial locality (& reduce compulsory misses)
+ have better transfer efficiency when transferring data from memory
  - less block transfer overhead per block
    the overhead: 1 address transmission & 1 memory lookup for a block of any size
  - amortize the overhead by transferring many words in 1 memory request
+ have less tag overhead (for the same size cache)
  - 64KB, direct-mapped, 4B blocks: 2^{14} tags (sets)
  - 64KB, direct-mapped, 16B blocks: 2^{12} tags
- have larger transfer latency
- might not access all the bytes in the block
  - have transferred the words from memory for nothing
- might increase capacity misses because bigger blocks means fewer blocks in the cache

Design Tradeoffs

Associativity

with a larger associativity:

+ higher hit ratio
  - more places to put data for a particular index value (reduces conflict misses)
  - more important for small caches
  - gains diminish as increase associativity
- slightly larger hardware cost
  - comparator for each block in the set
- increase in tag bits (decrease index bits)
- slightly larger cache access time (a MUX or a larger MUX)
- need block replacement hardware

Design Tradeoffs

Block replacement: which block you replace on a cache miss

- LRU (least recently used)
  - toggle between bit values for 2-way
  - counters for more associativity
- random
  - for example, low bits of the cycle counter
- little impact on performance

Design Tradeoffs

Memory update policy

- **write through**
  - update memory on each store (one word is written to memory)
  - \+ memory is always **coherent** (memory has the same value as the cache)
  - \- performance depends on the # of writes

Hiding write latency with write through

- **write buffer or store buffer**
  - contains data & its address until data is written to memory
  - CPU writes data into the cache & write buffer & then continues execution
  - memory is updated when the processor-memory bus is free
  - CPU must stall if the write buffer is full
- must check write buffer on a cache read miss: why?

Design Tradeoffs

Memory update policy

- **write back**
  - update memory when the block is replaced from the cache
  - \+ performance depends on the # of block replacements
  - \- add a **dirty bit** to each block's state
    - clear dirty bit when a block is read into the cache (**clean** block)
    - set dirty bit when the block is updated (**dirty** block)
    - on a block replacement, if the dirty bit is set, write the block to memory
    - performance depends on the # of **dirty block replacements** (even smaller!)
  - \- must do a tag check before the write to make sure this is the right block
    - if the block is one word, write-through can just write
  - \- takes more time than write-through
    - must check the tag before updating the cache
    - can you still do this in a single cycle?
  - \- memory is not coherent
    - must flush blocks from the cache before writing to disk

Hiding write latency with write back

- the dirty block can be buffered while the new block is being fetched
- replaced after control returns to the CPU

Design Tradeoffs

Cache contents

- **separate** instruction & data caches
  - + separate access ⟹ double the bandwidth
    - not have to stall the fetch if a load is at the same time
  - + shorter access time than 1 larger cache for both
  - + different configurations for I & D: *why?*
  - implemented as the first-level, on-chip cache
- **unified** cache
  - + lower miss rate if same size as the sum of the separate caches
    - more flexibility in where blocks can be placed
  - + less **cache controller*** hardware since only 1 cache

    (* logic that implements cache accesses, hits, misses)
  - implemented as the second-level cache

Cache Performance

Hit (miss) rate =

$$\frac{\text{\# references that hit (miss)}}{\text{\# references}}$$

- miss rate = 1- hit rate
- intermediate (component) metric
- measures how well the cache functions
- useful for understanding cache behavior relative to the number of references

Cache Performance

Average memory access time =

HitTime + MissRatio * MissPenalty

- always incur hit time because either:
  - a reference hits or
  - on a miss you access the cache again after the block is brought into the cache (this time it does hit!)
- (rough) average time it takes to do a memory reference
- performance of the memory system, including factors that depend on the implementation (the miss penalty)
- intermediate (component) metric

Miss penalty =

- send the address to memory +
- access the memory +
- transfer the data (block size (in words) * transfer time for 1 word)

  (assuming the bus is 1 word wide)

Execution Time

Including the memory system in execution time

$$\text{CPU time} = (\text{CPU execution cycles} + \textbf{memory stall cycles}) \times \text{cycle time}$$

(hit time is included in CPU execution cycles)

$$\textbf{memory stall cycles} = \frac{\text{memory accesses}}{\text{program}} \times \text{miss rate} \times \text{miss penalty}$$

$$\frac{\text{instructions}}{\text{program}} \times \frac{\text{misses}}{\text{instruction}} \times \text{miss penalty}$$

- might have different miss ratios for data & instructions

$$\frac{\text{misses}}{\text{instruction}} = \text{instruction miss rate} + \left(\text{data miss rate} \times \frac{\text{data references}}{\text{instruction}}\right)$$

- memory stall cycles are measured in CPU cycles
  - the faster the clock rate, the larger the miss penalty
- the lower the CPI, the greater the impact of memory stall cycles (Amdahl's Law in practice again)

Look at the performance examples on pp. 565-568
