

Where are we

- Recall our use of *evaluation contexts* to make a more concise operational semantics
- Now use that basic concept to
 - Implement interpreters more efficiently
 - Implement interpreters using more primitive operations
 - Define *continuations*
- Then "back to types"
 - Flavors of polymorphism
 - Start subtyping

<u>Review</u>

Evaluation contexts: expressions with 1 hole where "real work" occurs:

$$E ::= [\cdot] | E e | v E | (E, e) | (v, E) | E.1 | E.2$$
$$| A(E) | B(E) | (match E with Ax. e_1 | By. e_2)$$

Define "filling the hole" E[e] in the obvious way (see ML code). Semantics is now just:

$$E
ightarrow E$$
 $\overline{E[e]
ightarrow E[e']}$

$$\overline{(\lambda x.\ e)\ v \stackrel{\mathrm{p}}{
ightarrow} e[v/x]} \qquad \overline{(v_1,v_2).1 \stackrel{\mathrm{p}}{
ightarrow} v_1} \qquad \overline{(v_1,v_2).2 \stackrel{\mathrm{p}}{
ightarrow} v_2}$$

match
$$\mathsf{A}(v)$$
 with $\mathsf{A}x.\ e_1 \mid \mathsf{B}y.\ e_2 \xrightarrow{\mathrm{p}} e_1[v/x]$

match $\mathsf{B}(v)$ with $\mathsf{A}y. \ e_1 \mid \mathsf{B}x. \ e_2 \xrightarrow{\mathrm{p}} e_2[v/x]$

Theorem (Unique Decomposition): If $\cdot \vdash e : \tau$, then e is a value or there is exactly one decomposition of e.

Second Implementation

So far two interpreters:

- Old-fashioned small-step: derive a step, and iterate
- Evaluation-context small-step: decompose, fill the whole with the result of the primitive-step, and iterate

Decomposing "all over" each time is awfully redundant (as is the old-fashioned build a full-derivation of each step).

Now let's be more efficient...

<u>Maintain a stack</u>

We can "incrementally maintain the decomposition" if we represent it conveniently. Instead of nested contexts, we can keep a list:

$$S ::= \cdot \mid Lapp(e) ::S \mid Rapp(v) ::S \mid Lpair(e) ::S \mid ...$$

This new form of evaluation-context is a stack.

See the code: This representation is *isomorphic* (there's a bijection) to evaluation contexts.

Stack-based machine

Since we don't re-decompose at each step, our "program state" is a stack and an expression.

At each step, the stack may grow (to recur on a nested expression) or shrink (to do a primitive step)

Now that we have an explicit stack, we are not using the meta-language's call-stack (the interpreter is just a while-loop).

But substitution is still using the meta-language's call-stack.

Stack-based with environments

Our last step uses environments, much like you will in homework 3.

Now *everything* in our interpreter is tail-recursive (beyond the explicit representation of environments and stacks, we need only O(1) space).

You could implement this last interpreter in assembly without using a call instruction.

• Just need malloc

<u>Conclusions</u>

Proving each interpreter version equivalent to the next is tractable.

In our last version, every primitive step is O(1) time and space *except* variable lookup (but that's easily fixed in a compiler).

Perhaps more interestingly, evaluation contexts "give us a handle" on the "surrounding computation", which will let us do funky things like make "stacks" (called *continuations*) first-class in the language.

- "get current continuation; bind it to a variable"
- "replace current continuation with saved one"

<u>Continuations</u>

First-class continuations in one slide:

- $e ::= \ldots | \text{letcc } x. e | \text{ throw } e e | \text{ cont } E$
- $v ::= \dots | \operatorname{cont} E$
- $E ::= \ldots$ | throw E e | throw v E

$$E[\operatorname{\mathsf{letcc}} x. e] \to E[(\lambda x. e)(\operatorname{\mathsf{cont}} E)]$$

 $E[{
m throw}~({
m cont}~E')~v]
ightarrow E'[v]$

Very powerful and general: For example, non-preemptive multithreading *in the language*.

Where are we

- Have an operational model of functions, data structures, primitives, etc.
- Have a simple type system to ensure we use functions as functions, pairs as pairs, constants as constants, ...
- Digressed to:
 - compare types to logic
 - connect our textual rewriting to efficient implementations using stacks and environments
- Haven't done recursive types (e.g., lists) and exceptions.
 - Mutation on homework
- But first, be less restrictive without affecting run-time behavior

Being Less Restrictive

"Will a λ term get stuck?" is undecidable, so a sound, decidable type system can *always* be made less restrictive.

An "uninteresting" rule that is sound but not "admissable":

 $\Gamma dash e_1: au$

$\Gamma \vdash \mathsf{if} \mathsf{ true then } e_1 \mathsf{ else } e_2 : \tau$

We'll study ways to give one term many types ("polymorphism").

Fact: The version of ST λ C with explicit argument types ($\lambda x : \tau \cdot e$) has no polymorphism:

If $\Gamma \vdash e : \tau_1$ and $\Gamma \vdash e : \tau_2$, then $\tau_1 = \tau_2$.

Fact: Even without explicit types, many "reuse patterns" do not type-check. Example: $(\lambda f. (f \ 0, f \ true))(\lambda x. (x, x))$ (evaluates to ((0, 0), (true, true))).

My least favorite PL word

Polymorphism means many things...

- Ad hoc polymorphism: $e_1 + e_2$ in SML<C<Java<C++
- Ad hoc, cont'd: Maybe e_1 and e_2 can have different *run-time* types and we choose the + based on them
- Parametric polymorphism: e.g., Γ ⊢ λx. x : ∀α.α → α or with explicit types: Γ ⊢ Λα. λx : α. x : ∀α.α → α (which "compiles" i.e. "erases" to λx. x)
- Subtype polymorphism: new Vector().add(new C()) is legal Java because new C() has types Object and C

...and nothing.

```
(I prefer "static overloading" "dynamic dispatch" "type abstraction" and "subtyping")
```

Our plan

- Starting today: Subtyping, preferably without coercions
- Then: Parametric polymorphism (∀) and maybe first-class ADTs
 (∃) and recursive types (μ).
 (All use type variables (α).)
- Even later: Dynamic-dispatch, inheritance vs. subtyping, etc. (Concepts in OO programming)

Today's Motto: Subtyping is not a matter of opinion!

Record types

We'll use records to motivate subtyping:

Should this typecheck?

 $(\lambda x: \{l_1:int, l_2:int\}. x.l_1 + x.l_2)\{l_1=3, l_2=4, l_3=5\}$

Right now, it doesn't.

Our operational semantics won't get stuck.

Suggests *width subtyping*:

 $au_1 \leq au_2$

$$\{l_1:\tau_1,\ldots,l_n:\tau_n,l:\tau\} \leq \{l_1:\tau_1,\ldots,l_n:\tau_n\}$$

And one one new type-checking rule: Subsumption

$$\frac{\Gamma \vdash e : \tau' \qquad \tau' \leq \tau}{\Gamma \vdash e : \tau}$$

Permutation

Our semantics for projection doesn't care about position...

So why not let $\{l_1=3, l_2=4\}$ have type $\{l_2:int, l_1:int\}$?

$$\{l_{1}:\tau_{1},\ldots,l_{i-1}:\tau_{i-1},l_{i}:\tau_{i},\ldots,l_{n}:\tau_{n}\} \leq \{l_{1}:\tau_{1},\ldots,l_{i}:\tau_{i},l_{i-1}:\tau_{i-1},\ldots,l_{n}:\tau_{n}\}$$

Example with width: Show

 $\cdot \vdash \{l_1 = 7, l_2 = 8, l_3 = 9\} : \{l_2: \mathsf{int}, l_1: \mathsf{int}\}.$

It's no longer clear what an (efficient, sound, complete) algorithm should be. They sometimes exist and sometimes don't. Here they do.

Transitivity

Subtyping is always transitive. We can add a rule for that:

$$rac{ au_1 \leq au_2 \qquad au_2 \leq au_3}{ au_1 < au_3}$$

Or just use the subsumption rule multiple times.

Or both.

In any case, type-checking is no longer syntax-directed: Given

 $\Gamma \vdash e: au_1$, there may be 0, 1, or many ways to show $\Gamma \vdash e: au_2$.

So we could (hopefully) define an algorithm and prove it succeeds exactly when there exists a derivation.

Digression: Efficiency

With our semantics, width and permutation subtyping make perfect sense.

But it would be nice to compile e.l down to:

1. evaluate e to a record stored at an address a

- 2. load a into a register r_1
- 3. load field l from a fixed offset (e.g., 4) into r_2

Many type systems are engineered to make this easy for compiler writers.

Makes restrictions seem odd if you do not know techniques for implementing high-level languages. (CSE501)

Digression continued

With width subtyping, the strategy is easy. (No problem.)

With permutation subtyping, it's easy but have to "alphabetize".

With both, it's not easy...

$$egin{aligned} f_1:\{l_1: ext{int}\} & o ext{int} \quad f_2:\{l_2: ext{int}\} & o ext{int} \ x_1=\{l_1=0,l_2=0\} \quad x_2=\{l_2=0,l_3=0\} \ f_1(x_1) \quad f_2(x_1) \quad f_2(x_2) \end{aligned}$$

Can use *dictionary-passing* (look up offset at run-time) and maybe *optimize away* (some) lookups.

Named types can avoid this, but make code less flexible.

Depth Subtyping

With just records of ints, we miss another opportunity:

$$egin{aligned} & (\lambda x:\{l_1:\!\{l_3:\! ext{int}\},l_2:\! ext{int}\}.\ x.l_1.l_3+x.l_2)\ & \{l_1\!=\!\{l_3=3,l_4=9\},l_2\!=\!4\} \end{aligned}$$

Again, does not type-check but does not get stuck.

$$au_i \leq au_i'$$

$$\{l_1:\tau_1,\ldots,l_i:\tau_i,\ldots,l_n:\tau_n\} \leq \{l_1:\tau_1,\ldots,l_i:\tau_i',\ldots,l_n:\tau_n\}$$

(With permutation subtyping could just allow depth on left-most field) Soundness of this rule depends *crucially* on fields being *immutable*. (Depth subtyping is *unsound* in the presence of mutation.)

• Trade-off between power (mutation) and sound expressiveness (depth subtyping)

Function subtyping

Given our rich subtyping on records, how do we extend it to other types, namely $\tau_1 \rightarrow \tau_2$. For example, with width subtyping we'd like int $\rightarrow \{l_1:int, l_2:int\} \leq int \rightarrow \{l_1:int\}$.

$$\frac{???}{\tau_1 \to \tau_2 \leq \tau_3 \to \tau_4}$$

For a function to have type $\tau_3 \rightarrow \tau_4$ it must return something of type τ_4 (including subtypes) whenever given something of type τ_3 (including subtypes). A function assuming less than τ_3 will do, but not one assuming more.

Function subtyping, cont'd

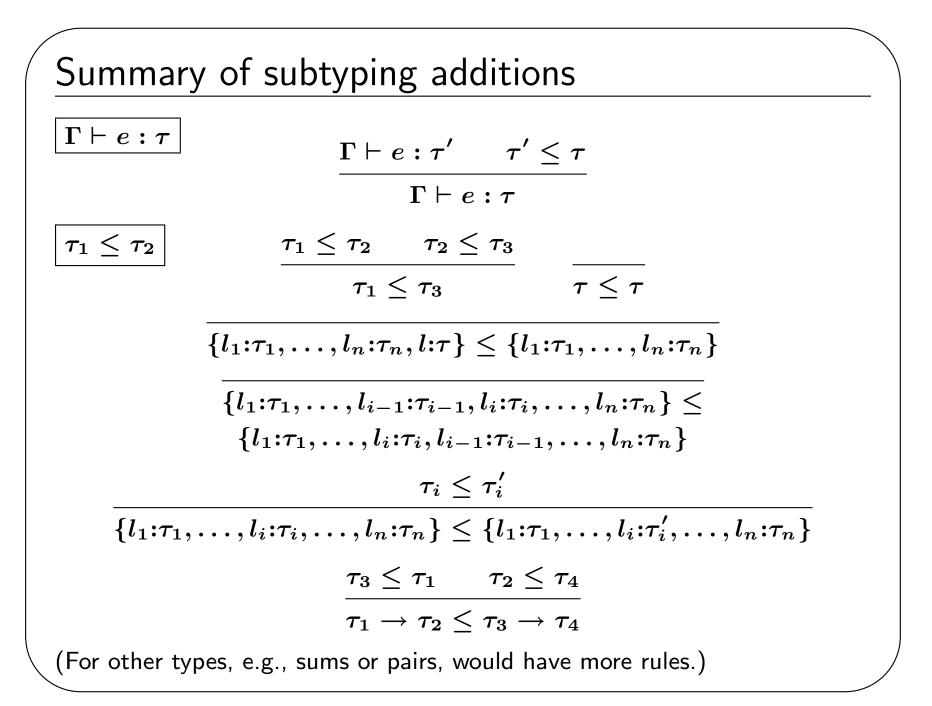

$$\frac{\tau_3 \leq \tau_1 \qquad \tau_2 \leq \tau_4}{\tau_1 \rightarrow \tau_2 \leq \tau_3 \rightarrow \tau_4} \qquad \qquad \text{Also want:} \quad \frac{\tau_2 \leq \tau_3}{\tau_1 \leq \tau_2}$$

Example: $\lambda x : \{l_1: \text{int}, l_2: \text{int}\}. \{l_1 = x.l_2, l_2 = x.l_1\}$ can have type $\{l_1: \text{int}, l_2: \text{int}, l_3: \text{int}\} \rightarrow \{l_1: \text{int}\}$ but not $\{l_1: \text{int}\} \rightarrow \{l_1: \text{int}\}.$

We say function types are *contravariant* in their argument and *covariant* in their result.

We say function types are contravariant in their argument *with our eyes closed*, **on one foot**, IN OUR SLEEP, and we never let anybody tell us otherwise. Ever.

(Depth subtyping means immutable records are covariant in their fields.)

Maintaining soundness

Our Preservation and Progress Lemmas still work in the presence of subsumption. (So in theory, any subtyping mistakes would be caught when trying to prove soundness!)

In fact, it seems too easy: induction on typing derivations makes the subsumption case easy:

- Progress: One new case if typing derivation · ⊢ e : τ ends with subsumption. Then · ⊢ e : τ' via a shorter derivation, so by induction a value or takes a step.
- Preservation: One new case if typing derivation · ⊢ e : τ ends with subsumption. Then · ⊢ e : τ' via a shorter derivation, so by induction if e → e' then · ⊢ e' : τ'. So use subsumption to derive · ⊢ e : τ.

Hmm...

Ah, Canonical Forms

That's because Canonical Forms is where the action is:

- If $\cdot \vdash v : \{l_1: \tau_1, \ldots, l_n: \tau_n\}$, then v is a record with fields l_1, \ldots, l_n .
- If $\cdot \vdash v: au_1
 ightarrow au_2$, then v is a function.

Have to use induction on the typing derivation (may end with many subsumptions) and induction on the subtyping derivation (e.g., "going up the derivation" only adds fields)

• Canonical Forms is typically trivial without subtyping; now it requires some work.
