

## CSE 326 Lecture 7: More on Search Trees

---

### ◆ Today's Topics:

- ⇒ Lazy Operations
- ⇒ Run Time Analysis of Binary Search Tree Operations
- ⇒ Balanced Search Trees
  - AVL Trees and Rotations

### ◆ Covered in Chapter 4 of the text

## From Last Time: Remove (Delete) Operation

---

- ◆ Removing a node containing X:
  1. Find the node containing X
  2. Replace it with:
    - If it has no children, with NULL
    - If it has 1 child, with that child
    - If it has 2 children, with the node with the smallest value in its right subtree, (or largest value in left subtree)
  3. Recursively remove node used in 2 and 3
- ◆ Worst case: Recursion propagates all the way to a leaf node – time is  $O(\text{depth of tree})$

## Laziness in Data Structures

---

- ◆ A “lazy” operation is one that **puts off work as much as possible** in the hope that **a future operation will make the current operation unnecessary**

## Lazy Deletion

---

- ◆ Idea: **Mark node as deleted**; *no need to reorganize tree*
  - ⇨ **Skip** marked nodes during Find or Insert
  - ⇨ **Reorganize** tree only when number of marked nodes **exceeds a percentage** of real nodes (e.g. 50%)
  - ⇨ **Constant time penalty** only due to marked nodes – depth increases only by a constant amount if 50% are marked undeleted nodes (N nodes    max N/2 marked)
- ◆ **Modify Insert** to make use of marked nodes whenever possible e.g. when deleted value is re-inserted
- ◆ Can also use lazy deletion for **Lists**

## Run Time Analysis of BST operations

---

- ◆ All BST operations (except MakeEmpty) are  $O(d)$ , where  $d$  is the depth of the accessed node in the tree
  - ⇒ MakeEmpty takes  $O(N)$  for a tree with  $N$  nodes – frees all nodes
- ◆ We know:  $\log N \leq d \leq N-1$  for a binary tree with  $N$  nodes
  - ⇒ What is the best case tree? What is the worst case tree?
- ◆ Best Case Running Time of Insert/Remove/etc. = ?
- ◆ Worst Case Running Time = ?
- ◆ Average Case Running Time = ?

## The best, the worst, and the average...

---

- ◆ For a binary tree with  $N$  nodes, depth  $d$  of any node satisfies:  
 $\log N \leq d \leq N-1$
- ◆ So, best case running time of BST operations is  $O(\log N)$
- ◆ Worst case running time is  $O(N)$
- ◆ Average case running time =  $O(\text{average value of } d) = O(\log N)$ 
  - ⇒ Can prove that average depth over all nodes =  $O(\log N)$  if all insertion sequences equally likely.
  - ⇒ See Chap. 4 in textbook for proof

## Can we do better?

---

- ◆ Worst case running time of BST operations is  $O(N)$
- ◆ E.g. What happens when you **Insert** elements in **ascending (or descending) order**?
  - ⇒ Insert 2, 4, 6, 8, 10, 12 into an empty BST
- ◆ **Problem**: Lack of “balance” – Tree becomes highly asymmetric
- ◆ **Idea**: Can we restore balance by **re-arranging** tree according to **depths of left and right subtrees**?
  - ⇒ Goal: Get depth down from  $O(N)$  to  $O(\log N)$

## Idea #1: Achieving the perfect balance...

---

- ◆ First try at balancing trees: Perfect balance
  - ⇒ Re-arrange to get a **complete tree** after every operation
- ◆ **Recall**: A tree is complete if there are no “holes” when scanning from top to bottom, left to right
- ◆ **Problem**: Too expensive to re-arrange
  - ⇒ E.g. Insert 2 in the example shown
- ◆ **Need a looser constraint...**

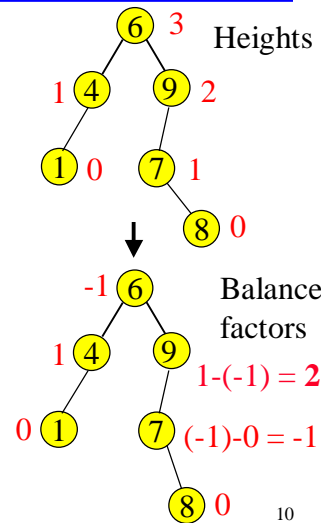

## Idea #2: Leave it to the professionals...

- ◆ Many efficient algorithms exist for balancing trees in order to achieve faster running times for the BST operations
  - ⇒ Adelson-Velskii and Landis (AVL) trees (1962)
  - ⇒ Splay trees and other self-adjusting trees (1978)
  - ⇒ B-trees and other multiway search trees (1972)

## AVL Trees

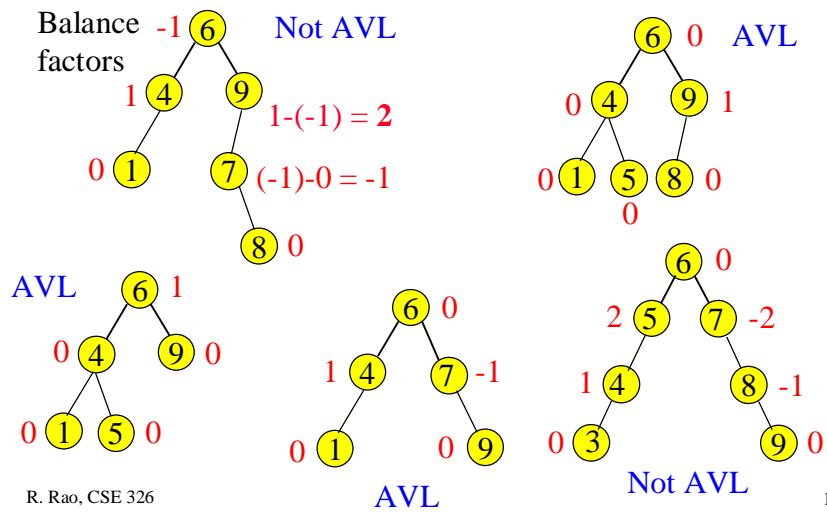

- ◆ AVL trees are height-balanced binary search trees
- ◆ **Balance factor** of a node =  $\text{height}(\text{left subtree}) - \text{height}(\text{right subtree})$
- ◆ An AVL tree can only have balance factors of 1, 0, or -1 at **every** node
  - ⇒ For every node, heights of left and right subtree differ by no more than 1
  - ⇒ Height of an empty subtree = -1
- ◆ **Implementation:** Store current heights in each node

## Which of these are AVL trees?

## AVL Trees: Examples and Non-Examples

## The good news about AVL Trees

- ◆ Can prove: Height of an AVL tree of N nodes is always  $O(\log N)$
- ◆ How? Can show:
  - ⇒ Height  $h \leq 1.44 \log(N+2) - 0.328$
  - ⇒ Prove using recurrence relation for minimum number of nodes  $S(h)$  in an AVL tree of height  $h$ :  
 $S(h) = S(h-1) + S(h-2) + 1$
  - ⇒ Use Fibonacci numbers to get bound on  $S(h)$  bound on height  $h$
  - ⇒ See textbook for details

## The really good news about AVL Trees

- ◆ Can prove: Height of an AVL tree of N nodes is always  $O(\log N)$
- ◆ All operations (e.g. Find, Remove using lazy deletion, etc.) on an AVL tree are  $O(\log N)$ ...
- ◆ ...except Insert
  - ⇒ Why is Insert different?

## The bad news about AVL Trees

---

No longer an AVL tree  
(i.e. not balanced anymore)

## Restoring Balance in (the life of) an AVL Tree

---

- ◆ **Problem:** Insert may cause balance factor to become 2 or  $-2$  for some node on the path from insertion point to root node
- ◆ **Idea:** After Inserting the new node,
  1. Back up to root updating heights along the access path
  2. If Balance Factor = 2 or  $-2$ , adjust tree by rotation around deepest such node.

## Rotating to restore Balance: A Simple Example

---

---

Next Class:

Rotating and Splaying for Fun and Profit
